**To:** submissions  
**Subject:** Application A1039 - Low THC Hemp as Food

Dear Food Standards,

I write to express my support for the proposed change to allow low THC hemp seed to be used as human consumption as in application A1039.

I have attached several presentations from the European Industrial Hemp Association that I am a member of since 2006 for the reference of hemp seed use for human consumption for your information;

1. Hemp Foods in North America and results from nutritional studies (Dr Gero Leson)
2. Hemp Food in the EU (Daniel Kruse)
3. EIHA statement – Seed for animal consumption (EIHA and associates)

Given the growing of low THC hemp in Australia is governed by several regulated bodies that include; national police checks, State department of Primary Industries and the Federal department of Health, I see the current regulated system as adequate in which to control non- low THC seed entering the human consumption cycle. All crops of low THC must undertake THC testing at different times throughout the growing process and have these tests confirm that the hemp grown is under the legislative limits to that of 0.3% before any harvested material is allowed to leave those fields.

We have worked closely with state government departments to ensue this strict regime allows for commercial production for both fibre and seed legally, specifically in the states of Victoria and Queensland where the limits are 0.5%

It would be of great benefit to the Bast Fibre Industry in Australia if the seed that is produced from one of its crops (low THC Industrial Hemp) was allowed to be used and create additional income for the farmers and processors to ensure that a sustainable industry can prosper and the consumers in Australia given the right to eat this nutritious nut as is the right in most other countries around the world.

We support the use of low THC hemp seed in food for human consumption in all states of Australia.

Please contact me on the details below if you have any question

Kind regards,

**Shaun Bailey**

# Hemp Foods in North America: Trends and Results from Nutritional Studies

*Gero Leson  
Leson & Associates  
Scientific Advisor CHTA  
November 2007*

# Overview: Hemp in North America

- U.S.: Commercial hemp farming remains illegal
- Canadian acreage in the Prairies has gradually expanded
  - with hick-ups: speculative overplanting in 2006, correction in 2007
- Driven by strongly growing demand for hemp foods in U.S. and Canadian markets (40% p.a.) average acreage needed to supply market in the next 2 years estimated at 10–12,000 ha (25–30,000 acres)
- New products, (protein powder, shakes, milk) dominate growth – moderate growth for hemp cosmetics
- Access to retail stores well established – mainstream recognition of hemp foods and their nutritional value still limited

# Trends in Canadian Hemp Acreage and U.S Retail Sales

# 2007 U.S. Retail Sales of Hemp Foods by Category

Hemp Foods / Category	Retail Sales 2007	Market Share	Growth 2006--> 07
Hemp Milk	\$ 3,053,700	15%	/
Total Oil	\$ 1,873,560	9%	11%
Total Nuts and nut butter	\$ 1,534,200	8%	10%
Total Protein Powder	\$ 4,784,520	24%	62%

industry interviews

# Overview: Hemp in North America

- Short seed varieties (Finola, Crag) and dual-purpose (USO-14) account for >95% of acreage.
- Seed yields have increased – average now ~670 kg/ha clean (600 lbs/acre). Typical yields with Finola on irrigated land: 1800 kg/ha, clean
- Seed production currently required to supply market demand: ~ 8000 MT/year

# Canadian Hemp Seed Production

	2006	2007
Hectares	19,458	4,684
%Finola	25%	50%
% USO 14	75%	50%
<b>Seed Production / Estimated Seed Yields</b>		
USO clean, MT	7,218	1,158
Finola clean, MT	4,072	1,960
Total clean, MT	11,289	3,119
Avg. Yield, clean (kg/ha)	580	666

Estimates based on acreage for each variety and field experience. Source: Kevin Friesen, Nov. 2007

# Nutritional Evaluation of Hemp Foods

- Market growth driven increasingly by perceived nutritional benefits
- Canadian Hemp Trade Alliance (CHTA) initiated, in 2004, research program on hemp nutrition and coordinates projects
- Funding by Canadian agriculture programs (ARDI, ADF) and industry members
- Comprehensive characterization of hemp seeds, nuts, seedcake and oil now completed
- Clinical study under way

# Objectives of Nutritional Characterization Program

- What's in there?  
Quantify major and minor nutrients in hemp seeds, nuts, seedcake and oil
- How valuable is hemp protein?
- How do hemp seeds compare to flax, soy, canola?
- Disseminate results and educate consumers and the media about the nutritional profile of hemp foods

# Project Scope

- Tested 30 samples of hemp seeds, oil, nut, protein flour, hulls
- Included Canada's 4 main commercial varieties: Finola, USO 14, USO 31, Crag + 1 Alyssa
- Analyzed samples for a range of nutritionally relevant parameters
- Conducted rat feeding trials to determine digestibility of hemp protein
- Research coordinated by
  - Dr. Jim House, U of Manitoba, Winnipeg
  - Dr. Roman Przybylski, U of Lethbridge, Alberta

# Summary of Products and Parameters Tested

Phytosterols	✓	✓	✓	✓	
Flavonoids	✓	✓		✓	
Lignans	✓	✓		✓	
Gluten		✓		✓	

# Overview of Results

## Composition of Hemp Seed Products

- Levels of Macronutrients (fat, fiber, protein) don't vary significantly with variety, more with maturity and growing conditions
- Carbohydrates in whole seeds are mostly dietary fiber, little sugar and starch
- Most fiber resides in the seed hulls
- Total fiber is predominantly insoluble fiber, particularly in protein powder

## Typical Composition of Hemp Seeds, Nuts & Seed Cake / Protein Flour

# Solubility of Dietary Fiber in Hemp Seed Products

# Fatty Acids in Hemp

- Hemp oil has a characteristic FA fingerprint. Somewhat variety dependent. Early (northern) varieties slightly higher in nutritionally relevant FA.
- All varieties have balanced omega-6/3 ratio close to the “ideal” ratio of 3
- Unlike any other cooking oil, hemp oil also has significant levels of “higher FAs”, GLA and SDA

# Major Fatty Acids in Hemp Varieties

■ ALA (Omega-3) ■ GLA (Omega-6) □ SDA (Omega-3)

For each variety,  
averaged over all  
test matrices and  
crop years

# Fatty Acids Spectrum of Hemp Seeds, other Nuts, Oil Seeds & Legumes

# Hemp Protein

- Hemp protein has a characteristic amino acid spectrum – variety has little effect
- Hemp protein contains all essential amino acids
- Unlike animal and soy protein, it is not “complete” because Lysine level is lower than needed by children 2–5 yrs to support body growth
- Hemp’s Amino Acid Score (a measure of amino acid balance) is slightly better than for other nuts
- For adolescents and adults hemp protein can be considered “complete”

# Hemp Protein

- Rat feeding trials showed that hemp protein is highly digestible – comparable to the reference protein “casein”. This also indicates low levels of antinutrients.
- Hemp nut protein is slightly more digestible than the protein in whole seeds and seed cake / flour.
- Hemp’s “Protein Digestibility Corrected Amino Acid Scored (PDCAAS, the established measure of protein quality) of more than 0.6 (for nuts) is higher than for other nuts and oilseeds yet below that for soy protein.
- Overall, hemp protein is highly digestible and reasonably well balanced, particularly for adults.

# Essential Amino Acids in Canadian Hemp Varieties

# Amino Acid Score of Hemp Seeds, Nuts and Seed Cake

# Amino Acid Score of Hemp Seeds for Different Age Groups

# Hemp Protein Digestibility Coefficients from Rat Feeding Trials

# Protein Digestibility Corrected Amino Acid Score of Hemp Products

**In Comparison:**  
**PCDAAS of**  
Almonds: 0.24  
Peanuts: 0.52

# Minerals, Vitamins and other Micronutrients

- Hemp seeds have a high ash content, even compared to other nuts and oilseeds  
--> they are good, very good or excellent sources of several key minerals:  
P, Mg, Mn, Fe, Zn, K
- Levels of these minerals do not vary significantly with variety
- Hemp seeds are good sources of several B1, B3 and B5-vitamins.

## Minerals, Vitamins (cont'd)

- Hemp oil provides high but not exceptional levels of tocopherols (Vitamin E complex).
- Gamma tocopherol dominates. While generally considered inferior to alpha tocopherol ("Vitamin E") recent research suggests it as superior antioxidant.
- Hemp seeds contain significant levels of several phytosterols.

# Major Minerals in Whole Hemp Seeds

# Minor Minerals in Whole Hemp Seeds

■ Sodium ■ Iron ■ Manganese ■ Zinc

# Minor Minerals in Nuts, Oil Seeds and Legumes

# Vitamins A & B by Hemp Variety

# Tocopherols in Oil from Hemp Varieties

# Tocopherols in Various Vegetable Oils

# Sterol Content in Hemp Oil

# Major Phytosterols in Nuts and Oil Seeds

# Gluten in Hemp Seeds

- 3 samples of hemp nuts and protein powder were tested for gluten
- All contained less than 10 ppm of gluten
- FAO considers foodstuff “gluten free” if it contains < 20 ppm.

==> Hemp seeds are “gluten free” – as expected for oil seeds.

Previous tests showing gluten in hemp seeds reflect contamination from processing equipment.

# Nutrient Intake

## via Hemp Seeds and Nuts

Good Source of Nutrient

Very Good Source of Nutrient

Excellent Source of Nutrient

# Summary

- Hemp Seeds are highly nutritious nuts that compare favorably with other nuts and oilseeds.
- Oil offers fatty acids in excellent Omega 6/3 balance & significant amounts of GLA & SDA
- Hemp protein is balanced and highly digestible
- Seeds, nuts & protein flour are good, very good or excellent sources of key minerals and vitamins
- Seeds and protein flour are very good sources of dietary fiber
- Versatility of available hemp seed materials make hemp an excellent basis for healthy diet and a range of food products

## Summary (cont'd)

- Results to be published in a comprehensive paper in early 2008.
- Clinical study on the effects of eating hemp oil or hemp nuts on key indicators of inflammation, cardiovascular and metabolic health soon to start at clinic in Oregon.

# Hemp Food in the EU

EIHA Conference, May 2011

Hempro  
Int.

# Hemp as Foodstuff

Hempro  
Int.

## Main Statement

The turnover with hemp foodstuff and corresponding raw material is increasing worldwide. Hempseeds, hulled hempnuts, hempoil and hemp protein powder are becoming more presentable – both in retail as well as in food industry.

# Hemp as Foodstuff

## Basic Products: Nuts, Oil

Hempro  
Int.

From a botanical perspective, the hemp seed is classified as a **nut** and is one of the **most valuable foodstuff** of the **world**.

- Hempnuts
  - whole nuts
  - hulled nuts

- Hempoil  
(pressed from hempnuts)

# Hempseed Advantages

## + Rich in polyunsaturated fatty acids:

- Supplier of omega-3 fatty acids in form of SDA
  - Supplier of omega-6 fatty acids in form of LA
- Helpful with illnesses metabolic and cardiovascular ailments

## + Rich in protein:

- Includes eight essential amino acids
  - Gluten-free
- Contributes to a healthy immune system and is easily digestible, even for consumers with digestion insufficiencies (Celiac disease)

## + Without allergens:

- Hempnuts contain no nut allergens
- also suitable for humans with nut allergy

## + GMO-free:

- Free of Genetically Modified Organisms
- Eco-friendly food source

# Hempoil –

## Comparision with other Oils

Hempro

# The Hemp Market EU

## Status EU:

- Problem: no actual statistics for hempseed used as raw material
  - Estimated around 5 – 10 % of hempseed production for food production, 90m - 95 % for animal feed
  - No specific information available about hempseed production
- Presumably many hundred tons of hempseed annually  
= many thousand tons of various end products

Source: nova-Institut (2006), BMELV (2004/2005)

# The Hemp Market EU

Hemp Cultivation Area in the EU (ha)

Source: nova-Institut (2011)

# The Hemp Market EU

## Status EU:

- 2000 - 2006 hemp cultivation area around 14000 - 18000 ha (due to stable fibre production)
- In that period seed production was approx. 6500 t/a
- Derived from the 6500 t = 6000 t for animal feed (bird-, fish-) and up to 500 t for foodstuff (oil) and in small amounts for cosmetics
- In spite of new studies of the hemp fibre in the EU (e.g. from nova-Institut) reliable data for seed production and hemp food consumption is still rare.

Source: Estimates nova-Institut (2006), BMELV (2004-2006), FNR e.V. (2006)

Table 1: Development of the European hemp seed market 2007-2011.

\*Mainly from China, \*\* Exports of processed hemp seeds to North-America (included in 2011 EU consumption).

# The Hemp Market EU

- Currently, relevant production in Eastern Europe only takes place in Ukraine (ca. 500 t/a), but is likely to increase.
- Of the 1,500 t of hemp seed exported from the EU, ca. 500 t were actually exported as processed hemp seeds to North-America.
- Recently increasing demand in the food market
- At the same time, supply decreased due to lower acreages in France (lower demand from the cigarette paper industry )
- Other grains/food materials increase in price (e. g. corn, wheat, rape etc.)
- The result are increasing prices: +30% compared to 2010 and +50% compared to 2009.

# The Hemp Market EU

Source: EPHA (2011)

# The Hemp Market Canada

## Status Canada:

- Canadian acreage expands gradually - with hick-ups
- Sharp fall in 2007 to 4000 ha because acreage increased faster than the market in 2006
- Hempseed storages were still filled in 2007 with seeds from last year. Therefore acreages were reduced in 2007. But the demand is still increasing, so after 2008 there is an upward trend again.

Source: CHTA (2011), Hemp Oil Canada Inc. (2011)

# The Hemp Market Canada

Canada Hemp Cultivation Area (ha)

Source: EIHA (2011), CHTA (2011), Hemp Oil Canada Inc. (2011)

# The Hemp Market Canada

## Status Canada:

- From 2002 seed production: approx. 3500 t hempseed; since then high increase
- Derived from the 10,000 t (2011) approx. 1,700 t for hemp oil production and 5,500 protein powder, 2,800 t for hulled seed
- Virtually all production for seed – no utilization of fibre!
- More than 60% of acreage is certified organic
- 90-95 % of hempseeds target the food market

Source: CHTA (2011), Hemp Oil Canada Inc. (2011)

# The Hemp Market

## Comparison EU/Canada

Source: Estimates nova-Institut (2006) / Hemp Pro Int. (2011)

## Challenges

- **Quality:** e.g. ffa (free fatty acids indication number), cleaning, drying etc.
- **Availability (Supply):**
  - Increase of desired amounts, only stepwise possible
- **Countries of origin:**
  - Germany, but only small amounts
  - France provides high quality seed, but expensive
  - East Europe and China gain importance as seed distributors, but yet with certain quality problems
- **Marketing:**
  - Achieve greater attention in trade and with customers
  - No standard customer information available
  - The hemp foods hardly reach German supermarket chains
  - Abroad, integration in supermarket assortments (product design)

# Future Prospects

- North American data shows that high sales turnover and substantial amounts can be achieved.
  - ➔ Good perspectives for the EU market
- In Great Britain, Canada and USA, hemp already belongs to the standard sortiment in supermarkets
  - ➔ This should also be possible in the EU and other countries e.g. Germany.
- Example: If only 10 % of the population in Germany would integrate 10 ml of hemp oil in their daily nutrition, a yearly requirement of approx. 30 million litres of hemp oil e.g. 100 000 t of hemp seed would result.

# Thank you for your attention! Hemprow Int.

## 1. Background

Following a request from the European Commission, EFSA was asked to deliver a scientific opinion on the safety of hemp (cannabis) for use as animal feed.

EFSA suggested to put whole hemp plant-derived feed materials on the list of materials whose placing on the market or use for animal nutritional purposes is restricted or prohibited and to introduce a maximum THC content of 10 mg/kg to hemp seed-derived feed materials.

This suggestion is based on a LOEL (lowest observed effect level) of THC in humans of 0.04 mg THC/kg bw. By applying an uncertainty factor of 100, a PMTDI (provisional maximum tolerable daily intake) of 0.0004 mg/kg body weight (bw) was derived.

## 2. Summary of the EIHA statement

The European Industrial Hemp Association (EIHA) welcomes the establishment of guidelines for the THC concentration in animal feed by the European Commission.

EIHA would like to comment on the LOEL and the uncertainty factor suggested by EFSA and proposes in contrast to EFSA a LOEL of 0.07 mg THC/kg bw a day and an uncertainty factor of 20. The LOEL is based on two doses of 2.5 mg THC that is 5 mg per day (70 kg body weight), resulting in an acceptable daily intake (ADI) of 0.0035 mg/kg bw for THC. EIHA does not see much scientific basis for a maximum tolerable daily intake to be provisional and derive a PMTDI since the toxicology of THC is very well investigated in humans, compared with other toxins.

***Guideline for maximum THC content to hemp feed materials for farm animals like poultry, pigs, cows and fish, used for food production (meat, milk, eggs)***

**Based on the derived new LOEL and ADI values and following the methodology of EFSA this would lead to a maximum THC content of 100 mg/kg to hemp seed-derived feed materials.**

Furthermore we don't see any reason to prohibit whole hemp plant-derived feed materials in general. Because those feed materials can be used in a five to ten times higher share (up to 100%) in animal feed, we propose a **maximum THC content of 10 mg/kg to whole hemp plant-derived feed materials.**

## 3. Summary of the rationale for the derivation of the acceptable daily intake (ADI) suggested by EIHA

### 3.1 Summary of the rationale for the LOEL suggested by EIHA

- The lowest single oral THC dose, at which acute adverse effects, i.e. slightly reduced psychomotor performance, is usually in the range of 5-15 mg. In a few cases 2.5 mg THC, which usually is not distinguishable from a placebo, may cause psychotropic or psychomotor effects. Given that THC effects at low doses (5-20 mg/kg) on psyche and psychomotor performance usually do not last longer than 4-6 hours after oral intake (see Figure 1) two doses of 2.5 mg a day may be taken without increasing adverse effects. This results in a LOEL of 0.07 mg a day for a body weight of 70 kg.
- Adverse chronic effects, such as cognitive changes, structural brain changes, mutagenicity, carcinogenicity, significant changes to hormone levels in males and females, congenital effects, and adverse impact on child development were either not found in humans or were found only at doses significantly higher than the equivalent of oral doses of 10 mg/day, in which cases observed effects were moderate.
- As a rule, for most harmful chemicals the severity of a toxic effect is a function of cumulative exposure, i.e. its exposure concentration and its duration time (Gaylor 2000). Thus, the NOEL correspondingly decreases with the duration of exposure. In the case of THC, the opposite applies since the effect of a given exposure level decreases with time. This is due to the development of tolerance to THC at the cannabinoid receptors.

### 3.2 Summary of the rationale for the uncertainty factor suggested by EIHA

- Large clinical studies have shown that there is considerable interindividual variation in susceptibility to THC and that some adults may experience slight psychotropic or psychomotor effects at twice a dose of 2.5 mg (or 0.07 mg/kg bw), while most individuals show only effects at considerable higher doses. This variation may be based on genetic polymorphisms of the genes encoding the cannabinoid receptors and the enzymes responsible for the metabolism of THC. We suggest an uncertainty factor of 2 since an uncertainty of any origin is already largely taken into consideration by choosing a low LOEL.
- Since THC may easily cross the placenta to the foetus and the foetus may be more susceptible than children and adults we suggest an uncertainty factor of 5 for a possible higher susceptibility of foetuses and neonates with still not fully developed drug metabolizing enzymes. It is known from clinical studies that children tolerate higher doses of THC with regard to body weight compared to adults. In addition toxic effects from cannabis on the foetus, which have been observed in epidemiological studies are relatively low compared to other drugs. Therefore, an uncertainty factor of 5 should offer a sufficient margin of safety.
- Since the effects of THC may be potentiated by ethanol and other drugs in foetuses, newborns and adults we suggest an uncertainty factor of 2 for interactions with other substances. There is no hint for a measurable potentiation of THC effects with an oral dose of 2.5 mg twice daily by alcohol or other drugs. An uncertainty factor of 2 should offer a sufficient margin of safety.

- We do not suggest an additional uncertainty factor for different percentages of adipose tissue in different individuals as EFSA did, since obese subjects are not found among fetuses and newborns, which means that obese individuals are already protected by the uncertainty factor of 5 in this category. An additional uncertainty factor for obese subjects would only allow for additional protection of obese fetuses and newborns. However, the percentage of adipose tissue in fetuses and newborns is limited and compared to adults there is no large interindividual variation.
- These totals to an uncertainty factor of 20.

### 3.3 ADI suggested by EIHA

- Based on the above, an acceptable daily intake (ADI) for orally ingested THC of 0.0035 mg/kg bw was assumed to provide protection from both acute and chronic adverse effects to humans.

### 3.4 ADI versus PMTDI

EFSA suggests a provisional maximum tolerable daily intake (PMTDI), which is mainly based on discrepancies between animal studies and observations in humans concerning neuroendocrine effects. EIHA suggests an acceptable daily intake (ADI) since research conducted on neuroendocrine effects in humans do not justify the assumption that potential adverse effects may be underestimated and that the acceptable daily intake should be provisional.

## 4. Pharmacological and toxicological basis for the ADI as suggested by EIHA

### 4.1 Pharmacological basis for a LOEL

Several clinical studies have been conducted which allow the determination of a LOEL for THC. Lucas & Laszlo (1980) found pronounced psychotropic reactions (anxiety, marked visual distortions) in patients undergoing cancer chemotherapy that had received oral doses of 15 mg THC/m<sup>2</sup> (square meter of body surface) corresponding to 25 mg THC for an average adult (body surface: 1.7 m<sup>2</sup>). A reduction to 5 mg THC/m<sup>2</sup>, about 8-10 mg THC, produced only mild reactions. In a study by Frytak et al. (1984), oral administration of 15 mg THC to 38 cancer patients caused psychotropic effects in 58 % while 42 % experienced no effects. Brenneisen et al. (1996) administered single oral doses of 10 or 15 mg THC to two patients. Physiologic parameters (heart rate) and psychological parameters (concentration, mood) were not modified by the administration. The authors suggest a threshold for psychotropic effects of 0.2-0.3 mg/kg bw. In a study with patients suffering from spasticity due to spinal cord injury by Hagenbach et al. (2007) patients tolerated daily doses of 15-60 mg oral THC.

EFSA cited a study by Chesher et al. (1990) of a healthy population dosed orally with 5 mg of THC following a light breakfast. No difference in the subjective level of intoxication was found relative to placebo controls. Doses of 10 and 15 mg THC respectively caused slight differences relative to a placebo. An oral dose of 20 mg caused marked differences in subjective perception. In several clinical studies, psychotropic reactions were also observed following a single dose of 5 mg THC (Petro & Ellenberger 1981). However, these were generally indistinguishable from effects observed after the administration of placebos.

As pointed out by EFSA, at the lowest administered oral dose of 5 mg, Chesher et al. (1990) observed a decrease in several psychomotoric performance scores, primarily related to standing steadiness, reaction time, and arithmetic performance. It should be noted that the observed effects were small. Findings by other researchers suggest that even doses of 10 or 15 mg of orally administered THC generally result in minor psychomotoric effects (Brenneisen et al. 1996). With reference to the study by Chesher et al. (1990), where authors concluded that an effect on skill performances can occur with a single oral dose of 5 mg THC/person, EFSA suggests that this corresponds "to 0.06 mg/kg bw calculated for the highest individual body weight." EIHA suggests that a LOEL for THC should be based on two doses a day, since effects after oral administration usually last about 4-6 hours and the daily dose of THC in food is usually not consumed in one meal.

EFSA also refers to a review by Ramaekers et al. (2004) on isolated cognitive functions and psychomotoric skills related to driving performance to indicate that "THC at doses between 0.04 and 0.30 mg/kg bw causes a dose-dependent reduction in performance," as observed in different tests. However, most of these effects have been investigated after inhalation of THC (cannabis) and Ramaekers et al. (2004) stated that the "magnitude of the THC effects on performance furthermore varied with the application form, i.g. smoking or oral intake, and time post THC use." It is well-known that THC effects are

considerably stronger after smoking (inhalation), and that the lowest effect doses have been observed after smoking (see Figure 1). Thus, the review by Ramackers does not allow to derive a LOEL for THC of 0.04 mg/kg bw for oral intake as suggested by EFSA.

With regard to repeated exposure of THC EFSA refers to two studies by Beal et al. (1995, 1997), in which HIV patients received oral THC. The first study was a placebo controlled study with 139 patients, who received either THC (2 x 2.5 mg/person daily) or placebo for 42 days (Beal et al. 1995). The second study was an open long-term study, where patients received THC for 12 months (Beal et al. 1997). In the first study 25/72 (about 35 %) patients experienced psychotropic effects. In the long-term study similar effects were observed. However, an open clinical study is not very useful to assess psychotropic effects of THC since similar effects may be observed after placebo (see for example the study by Strasser et al. (2006) below).

EFSA states that "fewer reports are available on the effects of a repeated exposure to THC in humans" without citing any clinical study conducted in the past 10 years where several clinical studies, some of them large-scale, with oral THC and oral cannabis extracts with high concentrations of THC have been conducted (e.g. Wade et al. 2004, Strasser et al. 2006, Rog et al. 2005, Zajicek et al. 2003, 2005, Collin et al. 2007, Narang et al. 2008, Novotna et al. 2011). One of these cannabis extracts (Sativex) has recently been approved as a medicinal drug in the UK, Spain, the Czech Republic and Germany.

Strasser et al. (2006) investigated the effects of THC (2.5 mg twice daily) in cancer patients in a placebo controlled three-arm study with THC, a cannabis extract and a placebo. 243 patients were randomly assigned and 164 completed the six-week trial. In contrast to the study by Beal et al. (1995) with HIV patients, who received the same dose for the same period of time, no differences were observed between THC and placebo for THC-related toxicity and other effects. Thus, a THC dose of 2.5 mg twice daily may be usually regarded as a placebo dose with regard to toxic THC effects.

The largest clinical study ever conducted with THC was a 15-week three-arm study on THC, a cannabis extract and placebo in patients with multiple sclerosis (Zajicek et al. 2003). Patients were offered the possibility to continue into a 12-month follow-up study, which was also a double-blind placebo-controlled study (Zajicek et al. 2005). In the short-term study 611 patients and in the long-term study 502 patients were evaluable. In the short-term study doses were slowly increased up to the occurrence of side effects or until the maximum dose (10-25 mg THC/day depending on body weight) was reached. The maximum dose was 10 mg for participants with a body weight below 50 kg and 25 mg for those with a body weight above 89 kg. Mean daily doses after the dose finding phase for participants with a body weight of 50-69 kg was 11.5 mg (or 0.17-0.23 mg/kg bw) and for participants with a body weight of 70-89 kg 15.8 mg (or 0.18-0.23 mg/kg bw). Thus, mean daily tolerable doses were about 0.2 mg THC/kg bw.

Adverse event	Short-term study (15 weeks)			Long-term study (52 weeks)

Table 1: Side effects in the studies by Zajicek et al. (2003, 2005). Mean daily doses: about 0.2 mg/kg bw (see text for detailed information).

Compared to the short-term study the long-term therapy with THC over a course of 12 months resulted in a dramatic reduction of adverse effects (Table 1). This may be due to the development of tolerance for some symptoms and to the establishment of an individual tolerable dose for every patient. In the short term study doses were slowly increased until side effects appeared or the maximum daily dose was reached. Since several participants experienced side effects before reaching their maximum daily dose side effects were observed frequently. However, they were usually mild or moderate in intensity (Zajicek et al. 2003). In the long-term study by Zajicek et al. (2005) the incidence of side effects was no longer higher in the verum groups (THC and cannabis) compared to the placebo group except for the events "dizzy or lightheadedness" and "falls" (Table 1). In studies with THC taken by patients with HIV, similar observations of a reduction in frequency of side effects were made. While about 25% of patients reported a minor CNS-related adverse drug event during the first 2 weeks, only about 4% reported such an event during each of the following six weeks (Marinol prescribing information 2011).

**Conclusion:** An acute dose of 2.5 mg THC (corresponding to 0.035 mg/kg bw assuming a body weight of 70 kg) may usually be regarded as a placebo dose, albeit this dose rarely may cause mild psychotropic or psychomotor effects in humans. Usually only single doses of 5-15 mg THC cause mild psychotropic effects. 0.07

- **The effects of a single dose of THC typically last for 4 to 6 hours (see Figure 1). Thus, the ingestion of an oral dose of 2.5 mg of THC twice per day, equivalent to 5 mg taken over the course of a day, represents the LOEL for any psychotropic effects or the reduction in psychomotor performance. EIHA suggests 0.07 mg/kg bw as a reasonable LOEL for THC, which includes any increased susceptibility in certain individuals**

#### 4.2 Pharmacological basis for the uncertainty factor

EFSA argues that four factors should be considered as risk factors in deriving threshold limits for THC in humans: (1) Increased sensitivity of neonates and infants, (2) genetic polymorphisms, (3) interaction with other drugs, and (4) body mass index.

##### 4.2.1 Increased sensitivity of children, neonates and fetuses

Children are considered particularly sensitive to many harmful chemicals. Consequently, higher safety factors are chosen to provide adequate protection. However, clinical studies have indicated that children are less sensitive to the effects of THC effects (Abrahamov et al. 1995, Dalzell et al. 1986).

One study on cannabinoid receptor density (Glass et al. 1997) found a similar receptor density in the human foetus and children compared to adults. Other researchers have found that cannabinoid receptor density increases fivefold from birth to adulthood in rats (Belue et al. 1995). In another study low numbers of cannabinoid receptors could be observed as early as the 14th week of gestation in humans (Biegon & Kerman 2001). Receptor density increased slowly but did not reach adult levels by the end of the 24th week.

Glass et al. (1997) found that the fetal and neonatal human brains show patterns of receptor distribution similar to those observed in the adult human brain. They found a similar density of CB receptors in several parts of the brain (neocortex, cerebellum) and a greater density in children in other parts (midbrain, basal ganglia). The authors admit some limitations of their study: "Due to the small numbers of cases available for the study, it is not possible to draw any definitive conclusions on the precise levels of cannabinoid receptors

Figure 1: Time course of subjective effects following three modes of administration. A rating of the degree of "high" was made by subjects on a 0 to 10 scale (estimated from figures of Hollister et al. (1981) and Ohlsson et al. (1980)). Taken from Grotenhermen (2003).

binding within the developing brain. Also, since the fetal/neonatal and adult tissue was not processed together, considerable care must be taken in comparing the results of the fetal/neonatal studies with the results in the adult brains" (Glass et al. 1997).

These observations contrast to the results of a study by Belue et al. (1995), who found that cannabinoid receptor density in rats increases fivefold from birth to adulthood. Also, Rodriguez de Fonseca et al. (1993) found an increase in CB binding in rats between birth and day 30, followed by a slight decrease until adulthood (day 60 and later). Another group (McLaughlin et al. 1994) found that cannabinoid receptor mRNA (messenger ribonucleic acid) is present at adult levels as early as postnatal day 3, while CB binding increased almost 50% with increasing age. The last study may resolve some of the contradictions between the different studies since receptor density may be high in infants and children while receptor activity may be low.

In the study by Biegón & Kerman (2001), the pre- and postnatal distribution of human brain CB1 receptors was investigated using quantitative autoradiography with [(3)H]CP55,940 as a ligand. Normal fetal brains (N = 8, gestational age 14-24 weeks) were obtained from voluntary abortions and were compared with normal adult human brains (N = 16, age 18-78). In the fetal human brain, low densities of THC-displaceable, region-specific binding could be observed as early as 14 weeks gestation. Receptor density increased slowly with gestational age but did not reach adult levels by the end of the second trimester (24 weeks gestation). In addition, the distribution pattern in the fetal brains was markedly different from the adult pattern. The most striking difference was the very low density of binding in the fetal caudate and putamen. In contrast, the globus pallidus pars medialis has almost-adult levels of cannabinoid receptors by 17-18 weeks gestation. Authors concluded that "the relatively low and regionally selective appearance of cannabinoid receptors in the fetal human brain may explain the relatively mild and selective nature of postnatal neurobehavioral deficits observed in infants exposed to cannabinoids in utero."

Clinical studies have shown that children tolerate much higher doses of THC than adults before side effects become significant (Abrahamov et al. 1995, Dalzell et al. 1986). In one study, eight children, aged 3 to 10, who underwent chemotherapy, orally received 18 mg delta-8-THC per square meter of body surface, four times daily. Each child received an average of 60 doses, which caused only mild psychotropic side effects in two children and none in the other six. Thus, children with a body surface of 1.0 m<sup>2</sup> received 18 mg THC four times daily. Assuming a body surface of 1.8 m<sup>2</sup> for an adult, this corresponds to single doses of 30 mg and a daily dose of about 120 mg THC. Delta-8-THC is assumed to be somewhat less psychotropic than delta-9-THC, with a relative potency of approximately 75%. Thus, a single 30 mg delta-8-THC dose corresponds to about 23 mg of delta-9-THC, a dose at which adults usually experience considerable psychotropic effects. Authors suggest that the lower CB1 receptor density in children compared to adults may be responsible for the lower susceptibility of children to THC.

According to case reports of the Centre for Palliative Medicine and Paediatric Pain Therapy of the University of the Saarland (Germany) THC is an effective and well-tolerated medicinal drug in

the treatment of different severe illnesses in children (Gottschling 2011). All children received a slowly increased dose starting with a dose of 0.1 mg/kg bw, which efficiently avoided adverse effects. Mean THC dose was about 0.2 mg/kg bw in children with spasticity and pain after finishing dose finding.

In both humans and animals, transfer of THC to the vascular system of the foetus occurs across the placenta. The time course of THC-concentration in fetal blood is strongly correlated to that in maternal blood, though fetal plasma concentrations were found to be lower compared to the maternal level in rats (Hutchings et al. 1989), in sheep (Abrams et al. 1985-1986), in dogs (Martin et al. 1977), and in monkeys (Bailey et al. 1987).

Following oral intake of THC by the mother, the ratio between fetal and maternal THC levels in plasma appear to be much lower – about one to ten – compared to intravenous and inhalative THC intake, where fetal THC levels are about one third of the mother's. This is likely attributable to the difference in metabolic pathways between oral, inhalative (smoking), and intravenous administration. In a study on dogs, the brain of the fetus showed a THC concentration of one third of the mother's concentration half an hour after intravenous administration (Martin et al. 1977). This relation was also maintained with multiple administrations, indicating that the maternal plasma THC and not the fetal tissue is the actual source for the fetal plasma THC.

The only conclusive study on THC transfer following oral administration was carried out with rats (Hutchings et al. 1989). Two multiple-dose groups were administered either 15 or 50 mg/kg THC once daily during the last two weeks of gestation. Two single dose groups were given the same dose as above but only once on the last day of gestation. Sixty minutes after receiving the last dose, plasma THC levels of all dams and their fetuses were analyzed. Among the dams, plasma concentrations co-varied with dose, and multiple dosing produced higher concentrations than acute dosing, especially at the high dose. Among the fetuses, both in the acute and the chronic dosing group, plasma concentrations were approximately 10% of those found in the dams.

An additional difference between inhalative and oral intake is the much lower maximal peak concentrations of THC following the oral route. Inhalation of a single dose of 10-20 mg THC will result in THC peak plasma concentration in the order of about 50-100 ng/ml, whereas the same oral dose will result in a broader, less pronounced peak with maximum concentrations of typically 5 ng/ml (Grotenhermen 2003). This will also result in a lower broader THC peak in the fetal plasma. Since higher peak concentrations result in stronger effects for the same route of administration, it can be assumed that the fetus is less affected following oral ingestion, since oral and inhalative route of administration of the mother result in the same supply route for the fetus, i.e. the blood vessels of the umbilical cord.

This indicates that the absence of cognitive effects in the children of mothers who used oral cannabis in a Jamaican study (Dreher et al. 1994) may be due in part to the inefficient transfer, thus low fetal toxicity, of THC ingested by pregnant women.

**Conclusion:** Fetuses experience significant exposure to THC following maternal cannabis ingestion. However, due to different metabolic routes for oral and inhalative THC, fetal exposure after oral THC intake by the mother, e.g., with hemp foods, will be lower compared to inhalative THC intake by the mother, e.g., by smoking

	Inhalation (smoking a cannabis cigarette)	Oral intake (hemp)
Systemic bioavailability	20%	10%
Ratio of ingested THC to THC systemically available	1/5	1/10
Ratio of THC concentration in fetal and maternal plasma	1/3	1/10
Overall ratio	1/15	1/100

Table 2: Comparison of dose-specific fetal toxicity caused by maternal ingestion vs. inhalation of THC.

cannabis cigarettes. Assuming a systemic bioavailability of oral THC of about half that of inhaled THC (10 vs. 20%) and a fetus/mother plasma level ratio of 1:10, compared to 1:3 for inhaled THC, fetal exposure to THC ingested by the mother is about one-sixth of the exposure caused by the inhalation of the same dose (see Table 2). In addition, oral ingestion by the mother results in a much lower maximum peak concentration compared to inhalation of the same dose, further reducing possible impacts from THC. These differences in the transfer to the fetus between oral and inhalative uptake of THC thus provide an additional margin of safety from potential teratogenic effects.

#### 4.2.2 Genetic variation in the genes encoding CB receptors and metabolizing enzymes

There is considerable interindividual variation in the THC doses which result in pharmacological effects. This may be due to variations in polymorphisms of the specific genes (CNR1 and CNR2) that encode the most well-defined cannabinoid receptors (CB1 and CB2) and polymorphisms in the enzymes that are mainly responsible for the degradation of THC in the liver (mainly CYP2C9).

Sachse-Seeboth et al. (2009) investigated the impact of the CYP2C9 polymorphism on the pharmacokinetics of orally administered THC in 43 healthy volunteers. THC pharmacokinetics did not differ by CYP2C9\*2 allele status. However, the median area under the curve of THC was threefold higher and that of the metabolite THC-COOH was 70% lower in CYP2C9\*3/\*3 homozygotes than in CYP2C9\*1/\*1 homozygotes. CYP2C9\*3 carriers also showed a trend toward increased sedation following administration of THC. They concluded that “the CYP2C9\*3 variant may influence both the therapeutic and adverse effects of THC.” Four of the 43 volunteers were carriers of the CYP2C9\*3/\*3 variant with a median maximum THC concentration in plasma of 6.3 ng/ml compared to a median of 2.7 ng/ml in carriers of CYP2C9\*1/\*1. It is reasonable to believe that several patients in the large clinical studies conducted with THC in recent years were carriers of the CYP2C9\*3/\*3 and this fact might have been the reason that in some studies even doses of 2.5-5 mg twice daily may have caused psychotropic effects since these carriers may have presented with comparably higher THC concentrations in blood at these low doses compared to other patients.

#### 4.3 Pharmacological basis for deriving an ADI and not a PMTDI

EFSA states that “only a very limited number of the experimental studies performed in people” did address neuroendocrine effects, which is not quite true, since a large number of studies have been conducted, of which only two are cited in the EFSA review.

EFSA states that “a current risk assessment could only be

provisional and based on psychotropic effects observed in humans.” It refers to “the lack of conclusive data for neuroendocrine effects in humans” and hinting to a study by Wenger et al. (1988), who found neuroendocrine effects of THC at very low doses of 0.001 mg/kg bw/day administered intraperitoneally to rats, concluding that “the FEEDAP Panel cannot exclude that the provisional risk assessment underestimates potential adverse effects, in particular for fetuses and newborns.”

For more than 20 years an epidemiological study is conducted at the University of Pittsburgh, USA, with more than 700 children of mothers who used cannabis and other drugs during pregnancy. These children are examined regularly since their birth and results have been published since then in more than 20 papers (e.g. Scher et al. 1988, Gray et al. 2005, Day et al. 2006, Willford et al. 2010, Day et al. 2011). For more than 30 years a somewhat smaller epidemiological study with about 300 children is conducted at Carleton University in Ottawa, Canada, which resulted in an even larger literature on THC effects on fetuses in humans (e.g. Fried 1980, Fried 1995, Smith et al. 2004, Fried et al. 2005). Both longitudinal studies allow a good understanding of the consequences of THC exposure by the inhalation of cannabis to the foetus and the consequences to later life. It is no longer necessary to rely on studies with rats.

In addition, the relevance of animal studies, which found increased risk of stillbirth and other adverse effects on the fetus following peritoneal injection of THC, to humans, is in principal highly questionable. No such effects had been found with humans after oral or inhalative administration of much higher doses. The same applies to the reported impact of low THC doses on hormone levels in pregnant rats. There are several indications that the effects observed by Wenger and his colleagues should not be extrapolated to humans. E.g., in one of their studies (1989), i.p. injection of 0.001 mg/kg THC during the 3rd week of pregnancy in rats caused a significant prolongation of pregnancy and 42% of stillbirths. This contrasts strongly to studies in humans. There are many studies of pregnancy outcome in users of cannabis. None of them reported any increase of stillbirths relative to controls who did not consume cannabis or a prolongation of pregnancy.

Wenger and his colleagues also reported significant alterations following very low doses of intraperitoneally administered THC, including a reduced LH concentration after i.p. injection of 0.001 mg/kg THC over the 1st, 2nd or 3rd week of pregnancy in rats (Wenger et al. 1988). In contrast, Tyrey (1980) administered intravenous THC in doses of 0.0312 to 0.5 mg/kg to female ovariectomized rats and found no effects on LH secretion at the lowest dose of 0.0312 mg/kg

Target effect	Animal study	Human study
Male plasma testosterone hormone concentration	<ul style="list-style-type: none"> <li>0.1 mg/kg oral THC resulted in decrease in male rats (Steger et al. 1991).</li> </ul>	<ul style="list-style-type: none"> <li>0.15 mg/kg oral THC three times daily did not cause an effect (Dax et al. 1989).</li> <li>0.25 mg/kg inhaled THC three times daily did not cause an effect (Dax et al. 1989).</li> </ul>

Birth weight	<ul style="list-style-type: none"> <li>0.001 mg/kg intraperitoneally THC reduced birth weight in rats (Wenger et al. 1991).</li> </ul>	<ul style="list-style-type: none"> <li>Chronic cannabis use (about 0.1 to 2.0 mg/kg inhaled THC) did not cause reduced birth weight (Shiono et al. 1995, Dreher et al. 1994, several other studies).</li> </ul>

and significant effects at 0.0625 mg/kg and higher. It is unclear why an intravenous dose of 0.0312 mg/kg (corresponding to about 0.3 mg/kg oral THC with regard to bioavailability) should cause no effects while a 0.001 mg/kg THC dose should cause effects. Considering this contradiction in findings, EIHA suggests to dismiss the findings by Wenger and his colleagues until confirmed independently. It should be noted that the studies by Wenger et al. have been conducted more than 10-20 years ago and no other research group reproduced their findings during this time period.

Steger et al. (1990) found a significant decrease of plasma-LH and testosterone levels following doses of 0.1, 1.0 and 10 mg/kg THC in male rats. There was no dose-response relationship; all doses were equally effective. However much higher THC doses than 0.1 mg/kg had no effect on testosterone levels in humans. E.g., Dax et al. (1989) investigated the effects on male chronic cannabis users of administering orally three times per day 10 mg of THC or inhaling three times per day 18 mg of THC for three days, following at least two weeks of abstinence. These conditions simulate routine cannabis drug use. The researchers did not find any alterations in the plasma testosterone concentration. Mendelson et al. (1978) could not detect any influence on the testosterone level in 27 cannabis users that had consumed a mean of 54 cannabis cigarettes or 120 cannabis cigarettes over a period of 21 days.

In a National Institute on Drug Abuse (NIDA) Research Monograph, Mendelson et al. (1984) stated with regard to the effect of THC on female hormones: "It is clear from the foregoing that THC consistently produces significant changes in pituitary gonadal hormones, which are essential for normal reproductive function in

experimental animal models. The major unanswered question is: what is the relevance of these data for human females? There are often marked species differences even within animal models and the degree to which THC induced disruption of pituitary gonadal hormones in animals can be extrapolated to humans is an empirical question. Despite the predictive values (and relative economy) of studying drug effects in animals, the ultimate significance of these findings can only be determined in human studies" (page 105).

*Table 3: Selected discrepancies between animal and human data on THC.*

**Conclusion:** Toxicological data from animal studies can help to elucidate the toxicity of cannabinoids in humans. However, comparison of the data from studies on humans and animals reveals often considerable inconsistencies. These may result from not only interspecies differences, but also different routes of administration. Particularly, the suitability of the intraperitoneal route for extrapolation to oral and inhalative exposure has previously been questioned (Abel 1985). The findings by Wenger and his colleagues, which contradict findings from human studies applying much higher doses and using the more representative oral or inhalative routes, are a case in point. Thus, wherever possible, a quantitative risk assessment should be based on data from human studies. EIHA suggests to dismiss the results by Wenger and colleagues and to rely on extensive available human data.
